Quantum control is an important logical primitive of quantum computing programs, and an important concept for equational reasoning in quantum graphical calculi. We show that controlled diagrams in the ZXW-calculus admit rich algebraic structure. The perspective of the higher-order map Ctrl recovers the standard notion of quantum controlled gates, while respecting sequential and parallel composition and multiple-control.

In this work, we prove that controlled square matrices form a ring, thereby satisfying powerful rewrite rules. We also show that controlled states form a ring isomorphic to multilinear polynomials. Put altogether, we have completeness for polynomials over same-size square matrices. These properties supply new rewrite rules that make factorisation of arbitrary qubit Hamiltonians achievable inside a single graphical calculus.

1 Introduction

Controlling or branching to different possible linear maps, relations, or channels is important across quantum information and quantum computation, and has been studied through many different approaches. In quantum algorithms common techniques are block encodings [17, 27] and linear combination of unitaries [7], while a number of formalisations have included routed quantum circuits [35], the many-worlds calculus [6], categorifying signal flow diagrams [3], and classical and quantum control in quantum modal logic [30].

The question we are interested in is how quantum graphical calculi such as the ZX [9], ZW [10], and ZH [2] calculus can be augmented to support properties of quantum control. An early use of controlled state diagrams was for proving constructive and rational angle ZX calculus completeness [21]. More recently, controlled state and controlled matrix diagrams have been applied to addition and differentiation of ZX diagrams [20], differentiating and integrating ZX diagrams for quantum machine learning [38], Hamiltonian exponentiation and simulation [31], non-linear optical quantum computing [13], and fermion-to-qubit mappings [23]. To sum ZX diagrams, these works have used controlled states along with the W generator from the ZW calculus.

Given how useful controlled diagrams are, a natural question to ask is why they work: What their underlying mathematical structures are, and which equational rewrites they satisfy. Before descending into the details, we present the relationship between controlled matrices, and the conventional notion of quantum controlled gates. We show how to recover the latter from the former, through the higher-order map Ctrl that maps square matrices to controlled square matrices.

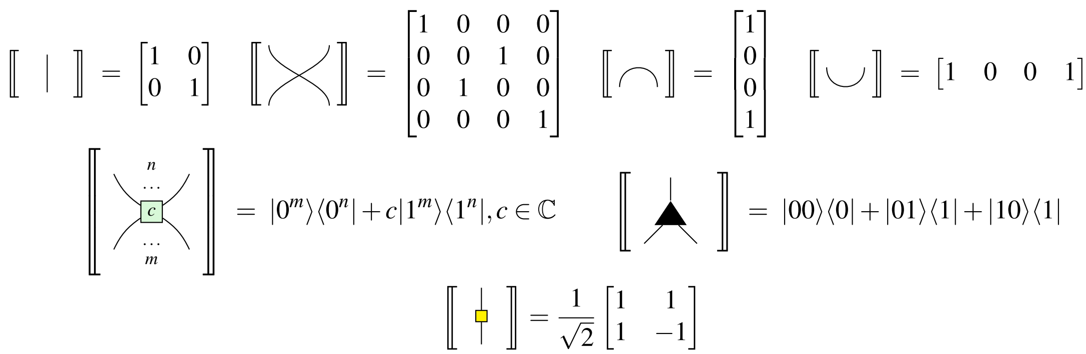
First of our main results, we show that the set of all controlled n-partite states defines a commutative ring. We introduce $\boxplus$ which defines an Abelian group and $\boxtimes$ which defines a commutative monoid, and show that $\boxtimes$ distributes over $\boxplus$. The fragment of the qubit ZW calculus corresponding to controlled states, which we call *arithmetic diagrams* hence defines a commutative ring which we prove is isomorphic to multilinear polynomials $\mathbb{C}[x_1,...,x_n]/(x_1{}^2,...,x_n{}^2)$. We prove completeness for all operations in this ring by an algorithm to rewrite any arithmetic diagram to what we call *polynormal form (PNF)*. Likewise, we show that the set of all controlled square matrices on n qubits defines a non-commutative ring ($\tilde{M}^n$,  , ), and we prove a second completeness result for this ring.

To the qubit ZXW-calculus, whose completeness for arbitrary finite dimension was proven in Ref. [26], we add controlled states and controlled square matrices as new generators, along with the rewrite rules for completeness over their rings. Now in the same calculus, we plug controlled states into each control wire of controlled square matrices, and show using only the rewrite rules so far that this is isomorphic to multivariate polynomials over same-size square matrices. Commutativity of controlled square matrices holds in the special case that the controls target mutually exclusive sectors, allowing copying of arbitrary controlled diagrams. As a result, we can factor multivariate polynomials over same-size square matrices. This third completeness result means we now have the ability to factor any Hamiltonian in the ZXW-calculus [31], even with all its terms black-boxed. In sum, these algebraic properties of quantum control give rise to powerful new graphical reasoning capabilities.

2 The ZXW-Calculus

This section introduces the qubit case of the ZXW-calculus, a graphical formalism for qudit computation which unified the ZX and ZW calculi and synthesised their relative strengths [26]. The ZXW-calculus consists of diagrams built from a small number of generators and equipped with a complete set of rewrite rules, which enables all equalities between linear maps to be proven diagrammatically. In this work, diagrams are read top to bottom and left to right.

The qubit ZXW-calculus is built from the following generators:

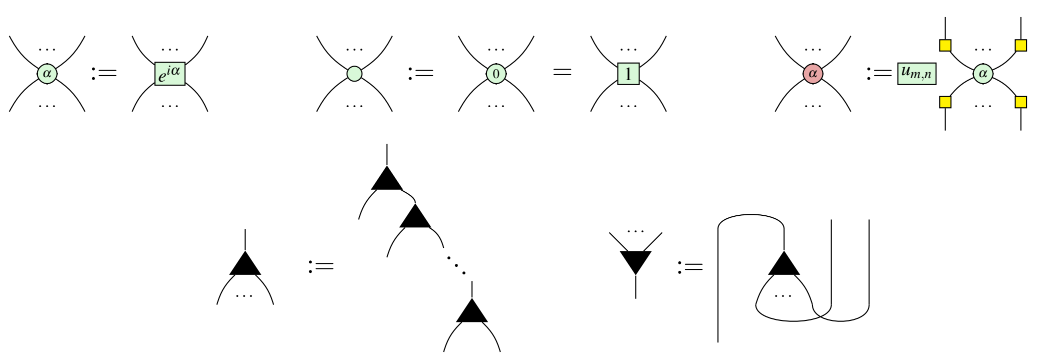


(2.1) $= \begin{bmatrix}1 & 0\\0 & 1\end{bmatrix}$, $= \begin{bmatrix}1&0&0&0\\0&0&1&0\\0&1&0&0\\0&0&0&1\end{bmatrix}$, $= \begin{bmatrix}1\\0\\0\\1\end{bmatrix}$, $= \begin{bmatrix}1&0&0&1\end{bmatrix}$

(2.2) $= |0^m\rangle\langle 0^n| + c|1^m\rangle\langle 1^n|, c \in \mathbb{C}$, $= |00\rangle\langle 0| + |01\rangle\langle 1| + |10\rangle\langle 1|$

(2.3) $= \frac{1}{\sqrt{2}}\begin{bmatrix}1 & 1\\1 & -1\end{bmatrix}$

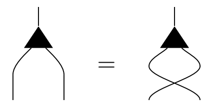
Diagrams can be composed vertically (sequentially) and horizontally (in parallel), which are interpreted as matrix multiplication $\circ$ and tensor product $\otimes$, respectively. For simplicity, we introduce the following notations:



where $u_{m,n} = d^{\frac{m+n-2}{2}} - 1$, such that the green box $\boxed{u_{m,n}}$ equals the scalar $2^{\frac{m+n-2}{2}}$.

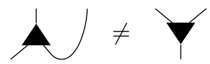
Equations in ZXW apply diagrammatic rewrite rules which prove equalities of the underlying matrices. Omitted from Figure 1 are the *structural rules* ubiquitous to quantum graphical calculi, such as that swapping twice yields the two-qubit identity and that an S-shaped cup and cap pair yields the one-qubit identity. These collectively are referred to as the *Only Connectivity Matters* rule, which governs that in this calculus the following operations preserve semantic equality: So long as all connections are preserved between all inputs, outputs, and generators of the diagram, the spatial position and orientation of each generator can be varied, and wires are free to cross or bend.

The Z and X generators are symmetric with respect to swapping two inputs, while the Z, X, and W generators are symmetric with respect to swapping two outputs:



(Sym)

However, unlike the Z and X generators, the W generator is not symmetric with respect to swapping an input and an output due to the following:



(Asym)

For this reason, care must be taken that exactly one wire of each W generator is unambiguously its exactly one input, drawn aligned with one point of the triangle.

The complete rule set of the qubit ZXW-calculus from Ref. [26], and our new rules for controlled states and controlled square matrices, are presented in Figure 1. Several important lemmas are found in Appendix B.

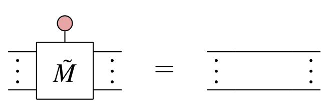
Remark 1. We work with the complete qubit ZXW-calculus in this work in order to connect usage of these results to the qubit ZX-calculus, such as the CX gate in Equation (4.3) and Hamiltonian operators explored in [31]. However, the proofs of completeness for arithmetic diagrams of this work use a subset of the qubit ZXW-calculus rules which also follow from the minimal ZW-calculus of [14], which were established after the main results of this work were found [1]. In the proof of Theorem 6.1, the only place we used (TA) was in the proof of Lemma 6.1. We could have equivalently replaced Equation (TA) with the equation of Lemma 6.1; and substituted the one-input, zero-output X spider with the one-input, zero-output W node as done in [14].

3 Controlled Diagrams

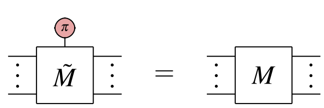
Following [31], we cover the definitions of controlled states and controlled square matrices, and arithmetic on them. Note that this is a different definition of controlled states to Ref. [20] in which controlling on $|0\rangle$ gives $|+\rangle^{\otimes n}$ instead of $|0\rangle^{\otimes n}$; this choice appears to make a substantial difference in the algebraic properties, which we discuss in Remark 4.

We define as a higher-order generator the controlled square matrix $\tilde{M}$, whose interpretation is entirely determined by the square matrix M by which is it labelled. In the next section, we show how this definition relates to standard notions of quantum controlled gates, by means of a higher-order map Ctrl that sends any square matrix M to its controlled square matrix $\tilde{M}$.

Definition 3.1. Any diagram satisfying both axioms below is called a *controlled square matrix* of the labelled square matrix M. We denote any such controlled diagram by $\tilde{M}$.



(CM0)



(CM1)

Remark 2. This definition can be applied irrespective of the dimensions of M so long as it is a square matrix. If working with only qubits then it is convenient to restrict to M being a $2^n \times 2^n$ matrix for some $n \in \mathbb{N}$, but this is not necessary for the definition of controlled square matrices.

We represent the additional dimension of $\tilde{M}$ as a vertical wire to distinguish it as the control wire. Interpreting this control wire as an input, because the interpretations of the generators of the ZXW-calculus from the previous

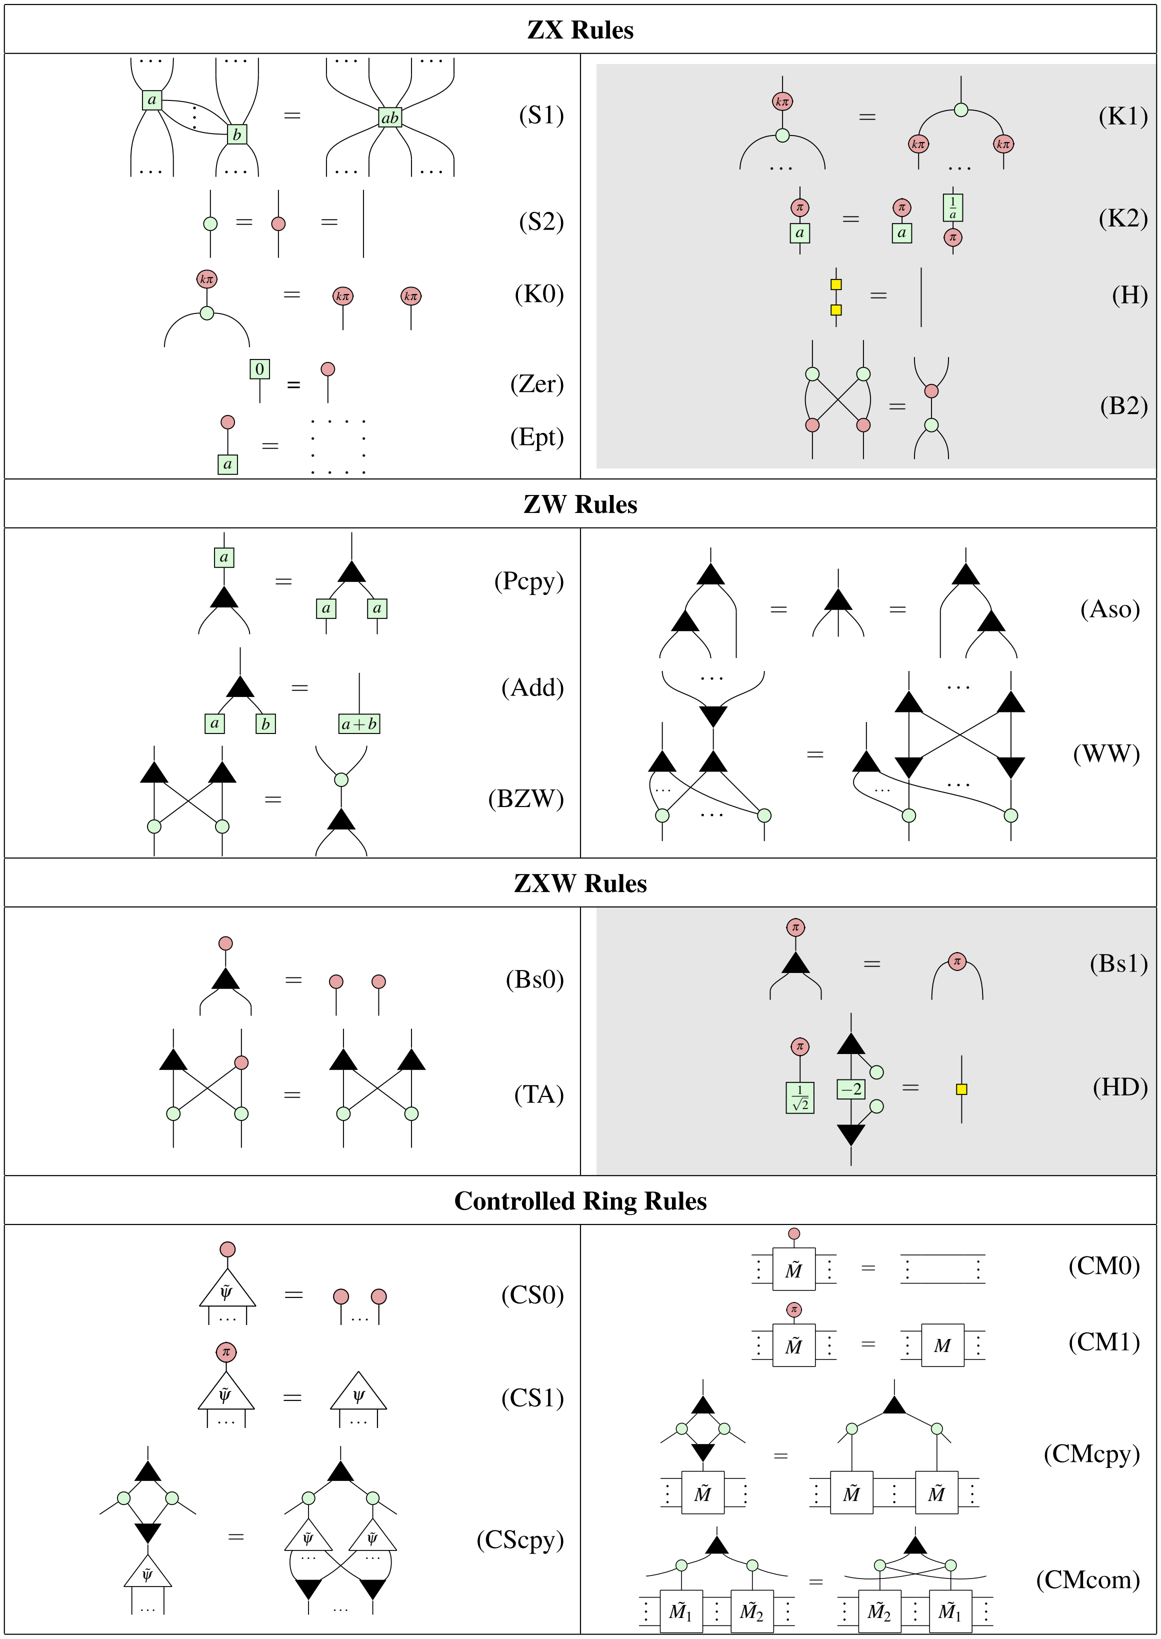


Figure 1: These ZX, ZW, and ZXW Rules are altogether complete for qubit linear maps, where $k \in \{0,1\}$ and $a \in \mathbb{C}$; we derive them by restricting the complete ZXW-calculus axioms for arbitrary finite dimension [26] to the qubit setting in Appendix C. Through Theorem 6.1 of this work, we show that these ZX, ZW, and ZXW Rules with white background form a complete set of axioms for *arithmetic diagrams* (Definition 6.1). By adding (CScpy) and (CMcpy), (CMcom), we then show that controlled states and controlled operators form polynomial rings, culminating in Theorem 7.1 achieving completeness and minimality for all operations over these rings.

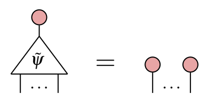
section fix that  $= |0\rangle$ and  $= |1\rangle$, the interpretation of any controlled square matrix $\tilde{M}$ is necessarily the linear map:

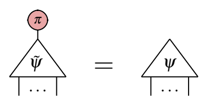
 $$= \langle 0| \otimes I + \langle 1| \otimes M = \begin{bmatrix} I & M \end{bmatrix} \tag{3.1}$$

Similarly, we can define higher-order controlled states as generators.

Definition 3.2. Any diagram satisfying both axioms below is called a *controlled state* of the labelled n-qubit state M. We denote any such controlled diagram by $\tilde{M}$.



(CS0)



(CS1)

Again, the interpretation of any controlled state as a linear map is entirely determined by the statevector of its labelled state ψ:

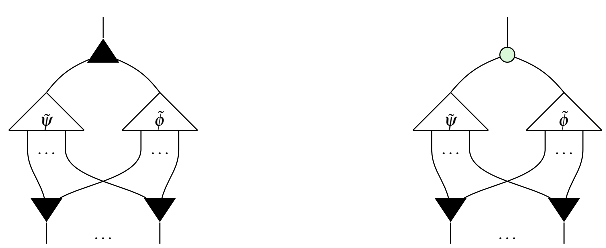
 $$= \begin{bmatrix} 1 & \vdots \\ 0 & \vdots \\ \vdots & \psi \\ 0 & \vdots \end{bmatrix} \tag{3.2}$$

Definition 3.3. Given controlled matrices $\tilde{M}_1, \ldots, \tilde{M}_k$ and $c_1, \ldots, c_k \in \mathbb{C}$, the controlled square matrices $\widetilde{\Pi_i M_i}$ and $\widetilde{\Sigma_i c_i M_i}$ are defined as follows:

Proposition 1 (Propositions 3.3 and 3.4 of [31])**.** The above diagrams are indeed the controlled diagrams for $\Pi_i M_i$ and $\Sigma_i c_i M_i$, respectively.

The addition and multiplication of controlled states are defined similarly to controlled matrix arithmetic, except that a layer of  s are appended at the bottom to preserve the number of outputs. The role of  is to *copy* controlled diagrams, as we will show in Section 5.

Definition 3.4. Given controlled states $\tilde{\psi}$ and $\tilde{\phi}$, we define addition $\tilde{\psi} \boxplus \tilde{\phi}$ and multiplication $\tilde{\psi} \boxtimes \tilde{\phi}$ operations on them to result in the controlled states:



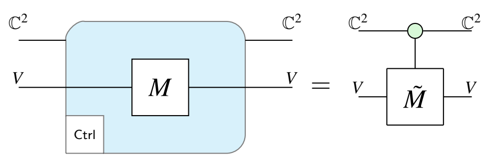
Remark 3. Ref. [31] defined this addition with red spiders at the bottom instead of $\blacktriangledown$ s; the linear map is the same, being $\widetilde{\phi+\psi}$. In choosing to use $\blacktriangledown$, we will soon define the arithmetic fragment of the ZW-calculus.

Removing the $\blacktriangledown$'s from the bottom of this multiplication gives the controlled diagram for the tensor product in Hilbert space $\widetilde{\psi \otimes \phi}$, as noted in Ref. [20].

Although the interpretation of $\tilde{\psi} \boxtimes \tilde{\phi}$ is not the controlled multiplication of the linear maps ψ and ϕ, nor as nice an expression in terms of ψ and ϕ, we will show in this work that this is in fact multiplication in the ring of *multilinear polynomials*.

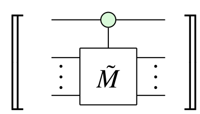
4 Quantum Control as a Higher-Order Map

In quantum circuits, quantum control is realised through controlled gates. In this section, we illustrate the correspondence between the controlled diagrams investigated in this work and the conventional concept of controlled gates in quantum circuits. Specifically, we can derive the latter as a special case of the former. We show this by reasoning with controlled gates through a straightforward construction on top of our ring of controlled square matrices. We define the higher-order map Ctrl which takes a square matrix $M : V \to V$ to its controlled square diagram $V \otimes \mathbb{C}^2 \to V \otimes \mathbb{C}^2$. In the functorial box notation of [24], we write



(4.1)

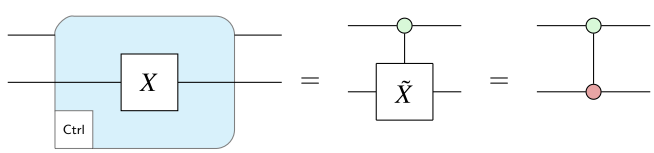
where



$$= \begin{bmatrix} I & 0 \\ 0 & M \end{bmatrix} \qquad (4.2)$$

Detailed exploration of control as a functor, extending props to controlled props, was independently carried out by Delorme and Perdrix in [15].

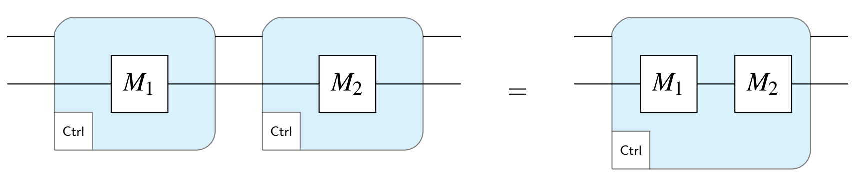
For example, the qubit CNOT gate precisely matches its definition of a controlled X gate because:



(4.3)

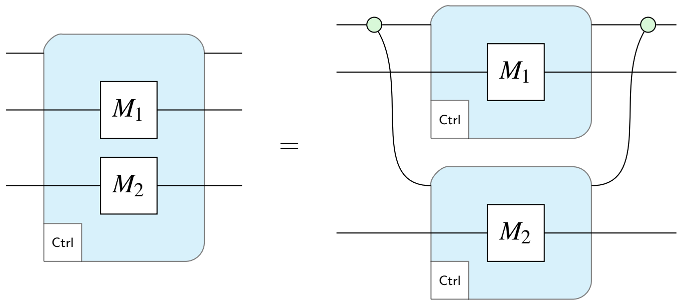
We prove in Appendix A that composition of controlled operations in sequence and in parallel is well-behaved.

Proposition 2.



(4.4)

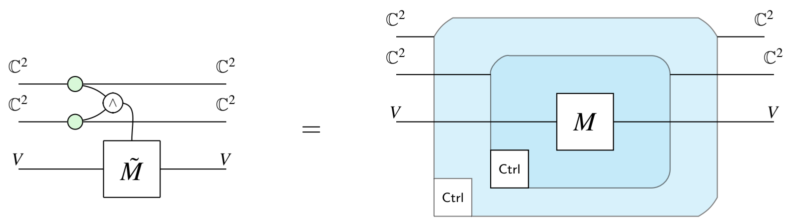
Proposition 3.



(4.5)

Furthermore, successive applications of Ctrl recovers the standard notion of multiple-control, which computes the AND of the control qubits:

Proposition 4.



(4.6)

5 Ring Axioms for Controlled Diagrams

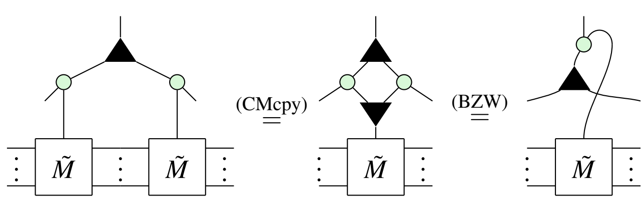
In this section, we reverse-engineer the underlying algebraic properties of controlled state and controlled square matrix diagrams. This builds up to diagrams for the unique normal form for states used for the first proofs of complete axiomatisation for qubit graphical calculi [18, 19]. All proofs in this section can be found in Appendix D.2.

Adding only the seven Controlled Ring Rules of Figure 1 to a complete qubit graphical calculus, suffices to derive the new completeness results of this work. All other equalities of diagrams in this paper were proven using only the rules in Figure 1. We verify the soundness of these rules for controlled diagrams in Appendix D.1.

5.1 Controlled Matrices

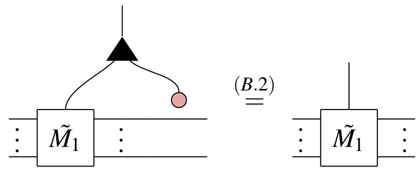
Let $\tilde{M}_n$ be the set of controlled square matrices on n qubits. The goal of this section is to prove that the addition and multiplication operations introduced above induce a ring on $\tilde{M}_n$. By Proposition 1, the addition and multiplication of controlled matrices is just the controlled addition and multiplication of the underlying matrices so the fact that the ring properties hold is not particularly surprising. What is more interesting is how easily these properties can be proven with a small subset of the ZXW rules. Likewise, we show that the set of controlled n-qubit states $\tilde{S}_n$ also forms a ring. The first rule enables us to copy controlled matrices.

For any square matrix M,



Now we show that controlled matrix addition and multiplication satisfy the ring axioms. Associativity of $+, \times$ follow immediately from (Aso, S1), respectively. Commutativity of addition is just (CMcom). If $M_1 \circ M_2 \neq M_2 \circ M_1$, then the controlled matrices will of course not commute either, so we cannot expect commutativity of multiplication in general. The remaining ring properties are as follows:

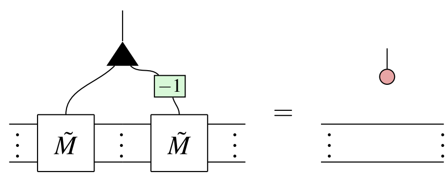
Lemma 5.1. *The additive identity is defined as*  $\otimes I_n$*:*



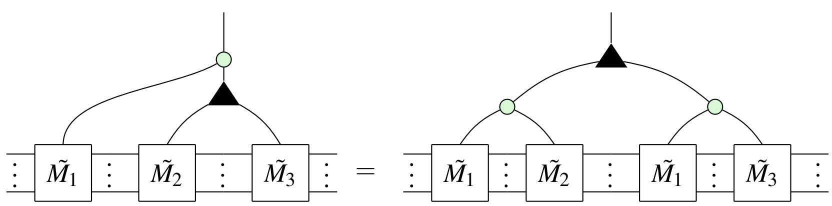
(5.1)

The multiplicative identity is defined very similarly as  $\otimes I_n$. The existence of additive inverses relies on the copying lemma from before.

Lemma 5.2. *The additive inverse of* $\tilde{M}$ *is built from* *:*



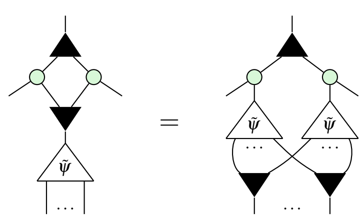
Lemma 5.3. *The addition and multiplication operations of controlled matrices distribute:*



Combining the lemmas of this section shows that controlled matrices form a non-commutative ring.

5.2 Controlled States

A similar result can be shown for controlled states, this time forming a commutative ring. Once again, we start with the ability to copy controlled states: for any state ψ,



(CScpy)

Then the remaining ring properties can be shown using diagrammatic rewrites.

Lemma 5.4. *For n-partite states* ψ_1, ψ_2*,* $\tilde{\psi}_1 \boxplus \tilde{\psi}_2 = \tilde{\psi}_2 \boxplus \tilde{\psi}_1$.

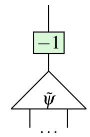
Lemma 5.5. *For n-partite states* ψ_1, ψ_2, ψ_3*,* $(\tilde{\psi}_1 \boxplus \tilde{\psi}_2) \boxplus \tilde{\psi}_3 = \tilde{\psi}_1 \boxplus (\tilde{\psi}_2 \boxplus \tilde{\psi}_3)$.

Next we have the additive identity.

Lemma 5.6. $\tilde{\psi} \boxplus \tilde{\mathbf{0}} = \tilde{\psi}$.

The additive inverse is defined similarly to the case of controlled matrices.

Lemma 5.7. *For a controlled state $\tilde{\psi}$, its additive inverse $\tilde{\psi}^{-1}$ is given by:*



Lemma 5.8. *For a controlled states $\tilde{\psi}_1, \tilde{\psi}_2, \tilde{\psi}_3$, $(\tilde{\psi}_1 \boxtimes \tilde{\psi}_2) \boxtimes \tilde{\psi}_3 = \tilde{\psi}_1 \boxtimes (\tilde{\psi}_2 \boxtimes \tilde{\psi}_3)$.*

Unlike for controlled matrices, we have also commutativity of addition.

Lemma 5.9. *For controlled states $\tilde{\psi}_1, \tilde{\psi}_2$, $\tilde{\psi}_1 \boxtimes \tilde{\psi}_2 = \tilde{\psi}_2 \boxtimes \tilde{\psi}_1$.*

Finally, we must prove distributivity.

Lemma 5.10. $\tilde{\psi}_1 \boxtimes (\tilde{\psi}_2 \boxplus \tilde{\psi}_3) = (\tilde{\psi}_1 \boxtimes \tilde{\psi}_2) \boxplus (\tilde{\psi}_1 \boxtimes \tilde{\psi}_3)$.

Remark 4. A different addition and multiplication for controlled states was defined in Ref. [21]. The definitions there corresponded to entry-wise addition and multiplication of statevectors, while our $\boxplus$ and $\boxtimes$ correspond to addition and multiplication of polynomials, which we show next.

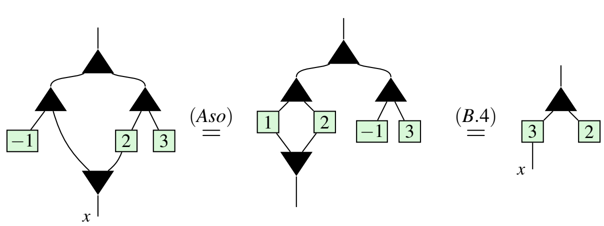
6 Isomorphism between the Ring of Controlled States and Multilinear Polynomials

Its been known since 2011 that , can be used to add and multiply number states a, respectively [11]. In the previous section we saw that , can moreover be used to copy controlled diagrams. In this section, we explain this connection by demonstrating that controlled states are in fact isomorphic to multilinear polynomials. This being a bijection is a well-known folklore result in the study of entangled states, but to the best of our inquiries we are not aware of a proof. More generally, Ref. [40] presented Cartesian Distributive Categories exemplified by polynomial circuits, which are isomorphic to polynomials over arbitrary commutative semirings or rings; their proof is non-constructive, giving explicit proof only for the case of Boolean circuits [39]. Our proof hinges on a normal form inspired by the proof of completeness for the ZXW calculus [26], as much of the expressive power of the ZXW calculus comes from this algebraic structure.

Firstly, we describe how to interpret certain ZXW diagrams as polynomials. Consider the diagrams:

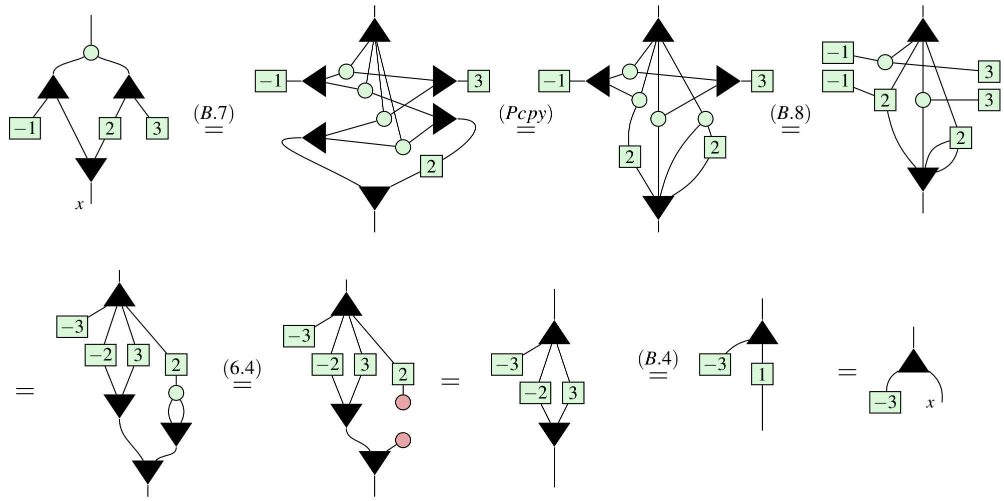
(6.1)

If we treat the bottom wires as an indeterminate x, we can read these bottom-up as computing $x-1$ and $2x+3$, respectively. Moreover, since these diagrams are both controlled states, they can be added together, yielding a diagram resembling $3x+2$:



(6.2)

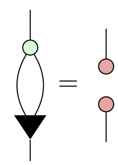
When trying to multiply these diagrams, rather than getting $(x-1)(2x+3) = 2x^2 + x - 3$, we instead get $x - 3$.



(6.3)

The reason for the missing $2x^2$ term is due to the following:

Lemma 6.1.



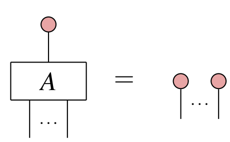
(6.4)

This lemma, proven in Appendix B, implies that $x^2 = 0$ for all variables x. Other than this, controlled state arithmetic appears to faithfully reflect polynomial arithmetic. To formalise this correspondence, we introduce the following definition.

Definition 6.1. A ZXW diagram with a single input on top is **arithmetic** if it contains only , wires, , , nodes and boxes.

To interpret an arithmetic ZXW diagram as an arithmetic expression, read as $+$, as $\times$, as the number a, as fanout and output/bottom wires as variables $x_1, \ldots, x_n$ numbered from left to right. The following lemma establishes that all arithmetic diagrams are controlled states:

Lemma 6.2. *For any arithmetic diagram A,*



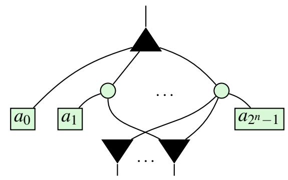
(6.5)

.

Proof. By definition, other than wires A contains only , , , and . This lemma holds when the arithmetic diagram consists of , , and , as a result of these generators recursively copying due to (Bs0, K0, B.2) respectively. Then considering arithmetic diagrams which also contain , as the other three generators copy , the lemma continues to hold through application of the axiom (Ept). $\square$

Just as it is typical to represent a polynomial in normal form as a sum of products, it is possible to rewrite every arithmetic diagram into a normal form as a single , followed by a layer of , followed by a layer of , .

Definition 6.2. An n-output arithmetic diagram is said to be written in **polynormal form** (PNF) if it is of the form:



(6.6)

The ith coefficient a_i is connected to the kth  iff the kth bit in the binary expansion of i is 1.

This normal form is familiar from completeness of all linear maps for qubits [19] and for qudits [26]. The reason we introduce the definition of a PNF is that it is an arithmetic diagram and therefore has a more immediate arithmetic interpretation. The reason for the specific connectivity condition is that it enables a diagram in PNF to directly represent its own matrix.

Proposition 5. The diagram in Equation (6.6) equals the matrix $\begin{bmatrix} 1 & a_0 \\ 0 & a_1 \\ \vdots & \vdots \\ 0 & a_{2^n-1} \end{bmatrix}$.

Proof. See Appendix E. □

Thus, every controlled state can be represented as at least one arithmetic diagram (namely, its PNF). Moreover, we now show that any other arithmetic diagram can always be rewritten to its PNF.

Theorem 6.1. *All arithmetic diagrams can be rewritten into PNF through application of ZXW-calculus rules. Therefore, the rules applied suffice for completeness for the arithmetic fragment of the ZXW-calculus.*

Proof. We present an algorithm to rewrite any arithmetic diagram to PNF in Appendix E. As with [26], this is sufficient for completeness since equality of diagrams reduces to writing both diagrams in PNF and then reversing one of the directions. □

Remark 5. All of the qubit ZXW-calculus rules [26] applied in this proof are derivable from the minimal qubit ZW-calculus rules from [14], derived independently from this work [1]. We can replace the TA rule with the rule of Lemma 6.1, and the qubit ZXW-calculus WW rule is derived in their [14, Lemma 23].

6.1 Isomorphism

At last we can prove the isomorphism. Recall that $\tilde{S_n}$ is the ring of controlled states with n outputs. Throughout, we shall let $\mathscr{P}_n$ denote the multilinear ring $\mathbb{C}[x_1,...,x_n]/(x_1^2,...,x_n^2)$.

Theorem 6.2. *There is an isomorphism $\mathscr{P}_n \simeq \tilde{S}_n$.*

First, we define the map $\phi_n : \mathscr{P}_n \to \tilde{S}_n$ before proving it induces an isomorphism. ϕ_n is defined to map an arbitrary polynomial $p(x_1,...,x_n) = a_0 + a_1x_n + ... + a_{2^n-1}x_1x_2...x_n$ to the PNF in equation (6.6).

Some important special cases are mapping scalars $a \in \mathbb{C}$ and indeterminates x_i:

$\phi_n(a) =$ 
$\phi_n(x_1) =$  $, \phi_n(x_2) =$  $, ..., \phi_n(x_n) =$  (6.7)

The proof that ϕ_n is a homomorphism resembles equations (6.2) and (6.3), but with greater generality. That ϕ_n is a bijection relies on Proposition 5. The full proof is found in Appendix E.

We end the section with a note that the arithmetic fragment of the ZXW-calculus defines a subcategory $\mathscr{A}$ of the base symmetric monoidal category (PROP) of the qubit ZXW-calculus. Adding to $\mathscr{A}$, this is an instance of a Cartesian Distributive Category as defined in Ref. [40].

Objects and Morphisms The objects of $\mathscr{A}$ are natural numbers $n \in \mathbb{N}$. The set of morphisms consists of arithmetic diagrams $f \in \mathrm{Hom}_{\mathscr{A}}(1,n)$ with exactly one input and n outputs, syntactically generated by the ZXW-calculus generators in Definition 6.1: $: 1 \to 1$, $: 2 \to 2$, $: 1 \to n$, $: 1 \to n$, $: 1 \to n$, and $\boxed{a}$ $: 1 \to 0$.

Note that multi-wire identities $\mathrm{id}_m : m \to m$ where $m \neq 1, m \in \mathbb{N}$ are outside this fragment, because $\mathscr{A}$ strictly admits only morphisms of type $1 \to n$ for any $n \in \mathbb{N}$.

Composition Two arithmetic diagrams $A : 1 \to m$ and $B : 1 \to n$, for $m,n \in \mathbb{N}$, can be composed in $\mathscr{A}$ in the following ways:

- Connecting any output of A as the input to B results in $(B \otimes id_{m-1}) \circ A : 1 \to m+n-1$. For the multilinear polynomial isomorphic to A, this performs variable substitution of that output of A, by the multilinear polynomial isomorphic to B. While this sequentially composes in $\mathscr{C}$ using id_{m-1}, the identity on $(m-1)$-qubits, id_{m-1} not being in $\mathscr{A}$ when $m > 2$ does not pose an issue, as the resulting composition remains an arithmetic diagram in $\mathscr{A}$.
- Connecting the inputs of A and B each to an output of results in a controlled diagram of type $1 \to m+n$, corresponding to adding their corresponding multilinear polynomials, which have no variables in common.
- Connecting the inputs of A and B each to an output of results in a controlled diagram of type $1 \to m+n$, corresponding to multiplying their corresponding multilinear polynomials, which have no variables in common.
- For any arithmetic diagram, connecting any $k > 1$ outputs each to an input of $: k \to 1$ reduces the number of output wires by $k-1$. This corresponds to identifying those variables of the multilinear polynomial to be the same. For example, if done after the above ways to add or multiply multilinear polynomials without variables in common, this furthermore enables adding or multiplying multilinear polynomials with shared variables.

7 Completeness for Factoring Controlled Operators

Our results so far show that controlled states and controlled square matrices each induce a ring structure, as they satisfy all ring axioms. Furthermore, the ring of controlled states is isomorphic to the ring of multilinear polynomials over complex numbers. What is the ring of controlled square matrices isomorphic to?

In this section, we will show that the ring of controlled square matrices is isomorphic to the ring of multivariate polynomials over same-size square matrices over the complex numbers, with complex number coefficients. Therefore, the former admits a completeness result over the latter.

In the previous section, the indeterminates of the multilinear polynomials were complex numbers represented by $\boxed{a}$. Consider them to instead be same-size matrices represented by controlled square matrix diagrams. Then:

Theorem 7.1. *Consider multivariate polynomials of the form $P = \sum_{i=1}^{m_i} c_i \Pi_{j=1}^{m_{ij}} M_{ij}$ over same-size square matrices $M_{ij} \in \mathbb{C}^{n\times n}$, where $n \in \mathbb{N}$, all $c_i \in \mathbb{C}$, and all $m_i, m_{ij} \geq 0$. Such polynomials are isomorphic to arithmetic diagrams whose outputs are each the control wire of same-size controlled square matrices $\widetilde{M_{ij}}$. The white background ZX, ZW, and ZXW Rules of Figure 1, along with* (CMcpy) *and* (CMcom)*, form a complete set of rules for all ring operations on these polynomials.*

Proof. We prove this by deriving a unique normal form, fixing an (arbitrary) order on the same-size square matrix variables. The algorithm to arrive at this normal form starts by rewriting the diagram sans the controlled square matrices to PNF, by the procedure of Theorem 6.1. Next, remove all $\blacktriangledown$'s by using (CMcpy) to make copies of the controlled square matrices. Finally, use (CMcom) to commute controlled square matrices whose controls act on mutually exclusive sectors past each other. The algorithm terminates with the controlled square matrix terms ordered by their mutually exclusive sectors in lexicographical order with respect to the order of their variables. The rules used here to derive this completeness result are the same subset of ZXW rules used for completeness for arithmetic diagrams in the ZXW-calculus in Theorem 6.1, plus the (CMcpy) and (CMcom) rules. □

Note these procedures enable controlled operators in mutually exclusive sectors to commute past each other. This does not apply to controlled operators in the same sector, which would require additional information about the operators themselves beyond being controlled operators, namely whether they commute.

Proposition 6. When using the minimal set of rules from [14] to prove the completeness result of Theorem 7.1 as described in Remark 5, adding the CMcpy and CMcom rules is also a minimal rule set, i.e. none of the rules are derivable from the others.

Proof. To show minimality, we can consider that the CMcpy and CMcom rules are the only rules here that involve the controlled square matrix generator, and so they cannot be derivable from the other rules here. The CMcpy rule can change the total number of controlled square matrices in the diagram, while the CMcom rule cannot. On the other hand, the CMcom rule can apply to two different controlled square matrices, changing their order where the outputs of one are inputs to the other; the CMcpy rule applies to two controlled square matrices only if they are labelled by the same matrix. □

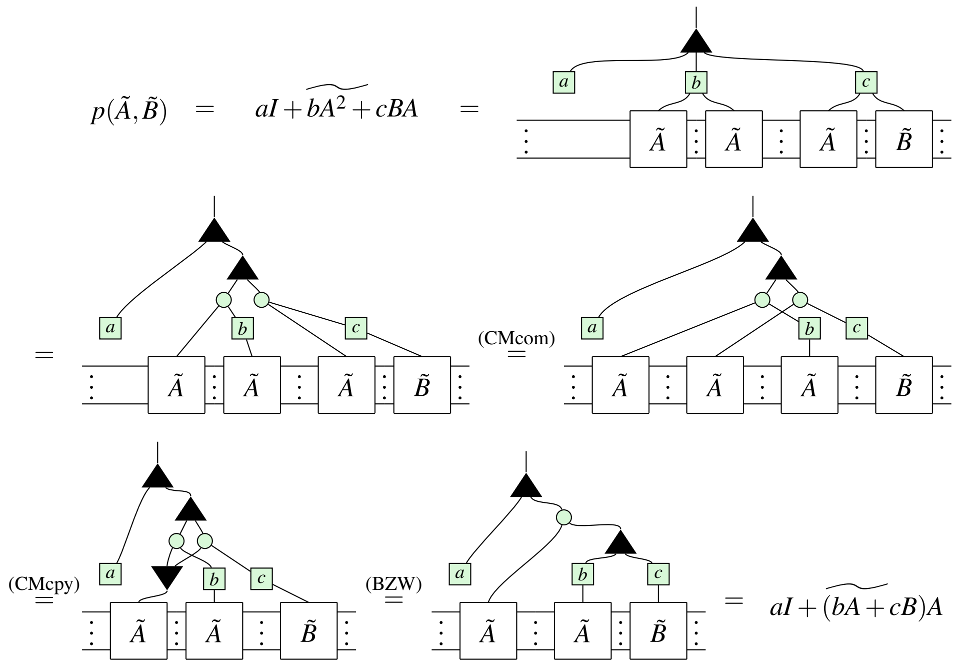
7.1 Factorising Hamiltonians

An application of Theorem 7.1 is that we can leverage our complete rules for arithmetic ZW diagrams and controlled diagrams to perform the equivalent ring operations to those on the corresponding multivariate polynomials. This is important for synthesising quantum circuits for a number of quantum algorithms whose constructions involve many controlled gates. These techniques are particularly amenable for quantum circuits derived from Hamiltonian operators, as is ubiquitous in quantum algorithms for quantum chemistry and condensed matter physics.

The earliest works on diagrammatic presentations of Hamiltonian operators include the Schrödinger equation, Taylor expansion, and Trotterization [31]; and diagrammatical differentiation and integration of parametrised quantum circuits applicable to analysing barren plateaus [38]. For Hamiltonians fully instantiated in terms of the ZX- or ZXW-calculus generators, including arbitrary qubit Hamiltonians that are expressible as linear combinations of tensor products of Pauli operators, the completeness results of these graphical calculi guarantee that any possible factorisations are derivable from the rules of the calculus.

However, while Hamiltonian operators are ultimately compiled to qubit Pauli operators if executed on qubit quantum computers, typically the physical systems of interest are not natively qubit systems. Controlled operators for non-qubit systems in quantum graphical calculi include spin-optical interactions [13], continuous-variable operators [32], fermion-to-qubit mappings [23], and SU(2) representations [37]. Ref. [23] notably used one of the new rules for controlled diagrams first proposed in this work, (CMcpy), to derive a general form for any two-body fermionic Hamiltonian in second quantisation under any linear encoding.

In this work, we introduce graphical rewrite rules that can involve and even copy black-box diagrams so long as they are controlled square matrices. To present a small working example, consider same-size square matrices I, A, B, and $a, b, c \in \mathbb{C}$. The equivalent ring operations for the below factorisation of an example Hamiltonian are performed directly on the controlled diagram.



(7.1)

The completeness results of the present work guarantee that for any Hamiltonian, the graphical rewrite rules of Figure 1 are capable of deriving any regroupings of the Hamiltonian terms. This may be generally of interest because factoring Hamiltonians reduces the Hamiltonian term count and therefore the circuit complexity, whereas expanding to unique polynormal form enables verifying that a given quantum computation indeed implements the desired Hamiltonian. When the control structure has the form of any arithmetic diagrams, then this guarantee holds even when no specific diagrammatic instantiation is fixed for the Hamiltonian terms, with the complexity of obtaining polynormal form moreover scaling as a function of the number of terms in the Hamiltonian. In contrast, naïvely applying the normal form procedure for the linear map itself scales as a function of the size of the matrix, which is exponential in the number of qubits.

8 Conclusion

To conclude, we proved completeness for all controlled n-partite states, which we showed form a commutative ring isomorphic to multilinear polynomials. Also, we showed that all controlled n-qubit square matrices form a non-commutative ring. Furthermore, we have completeness for plugging controlled states into the control wires of controlled diagrams, isomorphic to all multivariate polynomials over same-size square matrices, with application to factoring Hamiltonians. When the controls target mutually exclusive sectors, a rewrite rule can be applied to copy any controlled diagram, and thereby factor any Hamiltonian.

We have shown that every (controlled) state computes a polynomial; hence, we can interpret a universal fragment of the ZXW-calculus as corresponding to arithmetic circuits. This generalises Ref. [5], which found an algebraic interpretation of a certain fragment of ZW calculus. This line of reinterpreting quantum circuits as computing polynomials rather than unitary matrices offers a new perspective on quantum computation.

In another direction, we can apply completeness for polynomials isomorphic to controlled states to study entanglement. It can be easily shown diagrammatically that the polynomials corresponding to entangled (non-separable) states are exactly those that cannot be factored into irreducibles containing only variables corresponding to Alice's subsystem or only corresponding to Bob's subsystem. Since there are efficient algorithms for polynomial factorisation [16], this gives rise to a novel entanglement classification algorithm for pure states. Further developing this into a more refined algebraic theory of entanglement, building on the work in Ref. [1], could offer further insights.

We expect these results admit a natural extension for any controlled square matrices and controlled states in finite-dimensional Hilbert space, due to the completeness proof techniques of [26, 14, 25]. In all three of these works, while the central completeness result was for linear maps of higher- or mixed-dimensional Hilbert spaces, the normal forms themselves all involved restricting a qudit input to the W node to a qubit subspace of the qudit. Given the similarity of the ZW rules, we expect the underlying ring structures to be isomorphic even though [26, 25] and [14] differ in interpretation of the generators, where the W node of the latter is rescaled by multinomial coefficients relative to the former. Note that the completeness results of this work for controlled states do not directly follow from these completeness results for states, whose normal forms fix the control wire of the topmost W node to $|1\rangle$ instead of leaving this control wire open-ended.

As for when the control wires can take values beyond this two-dimensional subspace, we expect there to likewise be interesting underlying algebraic structure. A starting guess would be that if qudit controlled states also admitted an equivalence to multivariate polynomials, they would instead be modulo dth powers of the variables, of the form $\mathbb{C}^{d-1}[x_1,\dots,x_n]/({x_1}^d,\dots,{x_n}^d)$, due to the Hopf law between Z and W. Qudit multiple-control would likely have more complex structure than the qubit case here, considering the constructions for all prime-dimensional d-ary classical reversible gates and W states built in Refs. [42, 29, 41].

We are broadly interested in exploring the relations between controlled diagrams, controlled quantum circuits, and Hamiltonian operators. The completeness result for controllable quantum circuits established in [15] circumvents the unboundedness issues inherent to quantum circuits defined as a prop [8], indicating that control as a higher-order operation on quantum circuits is a powerful construction for equational reasoning. In this work, we rewrite controlled diagrams to their fully expanded polynormal form, therefore establishing that equational reasoning on the quantum circuits as diagrammatical objects [31] suffices to achieve any possible factorisations of Hamiltonian operators. While the completeness of the rules means these rules suffice to derive any equalities of quantum circuits, more work can be done on how to effectively apply these rules towards the objective of synthesising more compact circuit decompositions, particularly for multiple-controlled gates and for block encodings.

Moreover, we are curious about how to embed these new semantics for quantum controlled states and matrices into a functional programming language like in Ref. [28], and to interpret our diagrams in mixed-state quantum mechanics and relate them to the operational and denotational semantics for coherent control of Ref. [4] and to the channel construction of Ref. [12]. One approach is to consider using sector-preserving channels [34] and scoped effects [22] to more generally formulate semantics of multiple-control for heterogenous Hilbert spaces.

Yet another direction is to reconcile the interpretation of diagrammatic differentiation of our arithmetic polynomial circuits by the approach in Ref. [40], with that of quantum circuits and ZX diagrams in Refs. [33, 38, 20].

9 Acknowledgements

We thank Bob Coecke for motivating our exploration of these topics. We are grateful to all the collaboration with Matt Wilson in discovering the functorial properties of control. We thank Razin Shaikh, Harny (Quanlong) Wang, Itai Leigh, Tim Forrer, Aleks Kissinger, Frank (Peng) Fu, and Maxim van den Berg for insightful discussions. We also thank the anonymous reviewers who have given feedback on this work for their helpful comments. LY would like to thank the Google PhD Fellowship and the Basil Reeve Graduate Clarendon Scholarship at Oriel College for PhD funding at the University of Oxford, and the Tencent Post-Doctoral Research Fellowship at the University of Cambridge. RY would like to thank Simon Harrison for his generous support via the Wolfson Harrison UKRI Quantum Foundation Scholarship.

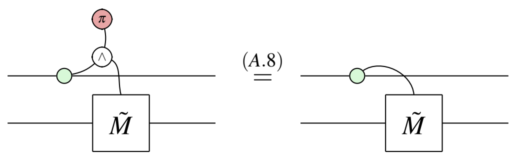
Verifying condition (CM1).



(A.12)

□

Since this is indeed the controlled matrix on a controlled gate, we obtain the required result by Equation (4.1).

Appendix B Basic Lemmas for Arithmetic Diagrams

In this section, we prove a number of lemmas used throughout the paper.

Firstly, we can define the one-input, zero-output W node to have the same syntax and semantics as the one-input, zero-output phase-free X spider, as done for arbitrary finite dimension in [14]. The remainder of this section proves a number of lemmas used throughout the paper that are all syntactic equalities, because they are derived purely through applications of the axioms of the qubit ZXW-calculus given in Figure 1.

Appendix C Derivation of the qubit ZXW-calculus axioms

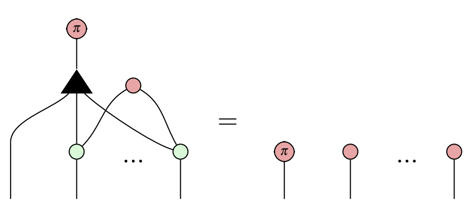
This section derives the axioms of Figure 1, purely through syntactic equalities of axioms directly sourced from the arbitrary finite dimension setting derived in [26], with the dimension then restricted to two to recover the qubit case. We then derived using these rules other simpler rules introduced by earlier works, notably [36], to choose simpler axioms complete for the qubit ZXW-calculus for Figure 1.

Some of the rules are trivial in the qubit setting and were thus disregarded in this work: $(D1)$, $(H1)$, (ZV), (VW) reduce to the same diagram on both sides of the equality, being identity. Likewise, the -1 multiplier which equals the identity in the qubit setting is omitted in the second equality of $(P1)$, here renamed to (H) to match the original rule name.

For (VA), adopting the semantically correct interpretation that the one-output W node is the identity — which moreover syntatically agrees with [14] — makes the equation trivial in the qubit setting. Since this one-output W node appears in neither the original qudit ZXW completeness paper nor anywhere in this paper, the (VA) rule can be safely disregarded in the qubit setting.

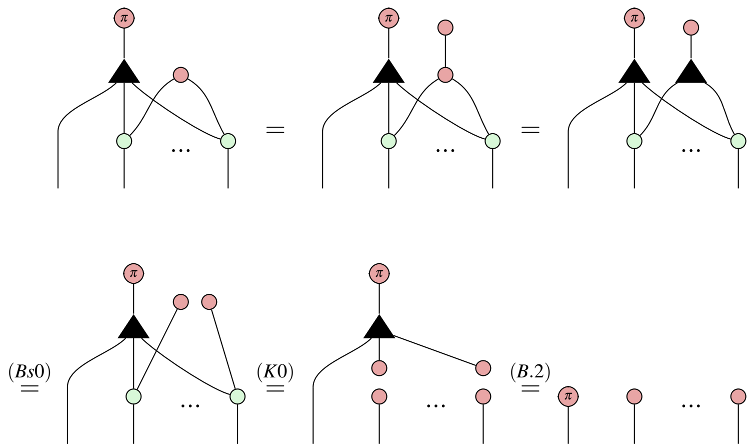
First we prove (KZ). This proof relies on the generalised (TA) rule from Lemmas 39 and 40 of [26], whose proof is identical in the qubit case. Note also that all multipliers on the LHS of (KZ) simplify to the identity.

Lemma C.1.



(KZ)

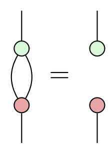
Proof.



□

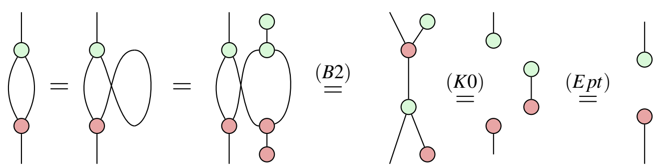
The remainder of this section is to derive (HD) from (HD) of [26], for which we first derive a number of lemmas.

Lemma C.2.



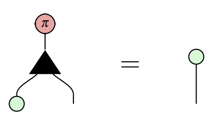
(C.1)

Proof.



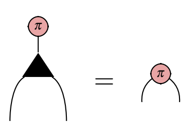
□

Next, we will prove $(Bs1)$ from the $(Bs1)$ rule of [26] restricted to the qubit setting, which is:



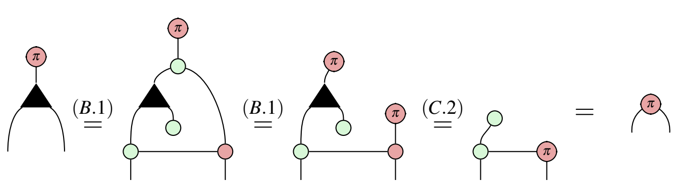
(C.2)

Lemma C.3.



(C.3)

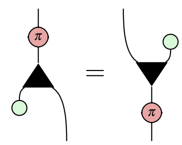
Proof.



□

Because we can derive the above lemma from Equation (C.2) (the $(Bs1)$ rule of [26] restricted to the qubit setting), and we can derive the latter from the former by simply applying $(K1)$, we have opted to replace the latter axiom with the former, which is simpler, in Figure 1.

Lemma C.4.



(C.4)

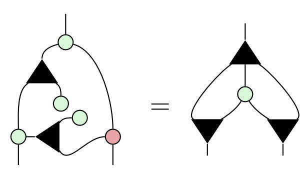
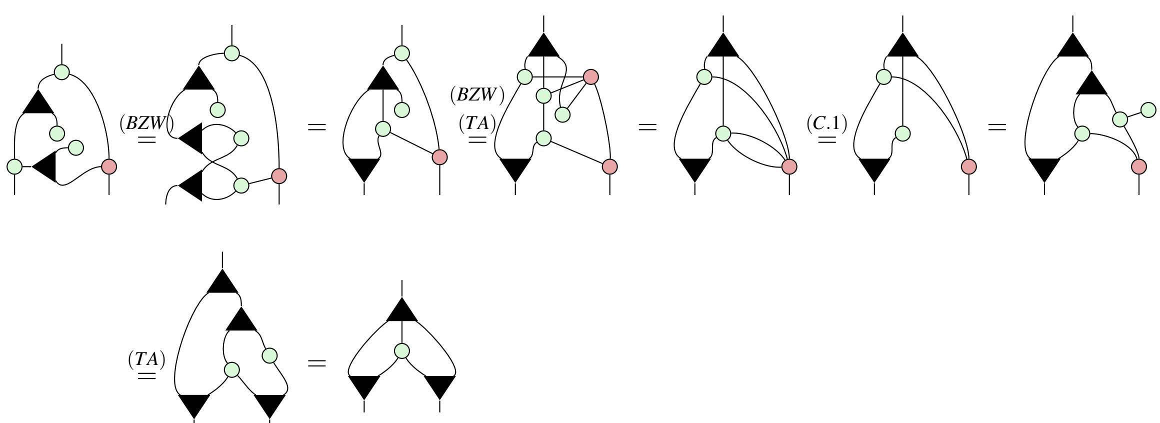
Lemma C.9.



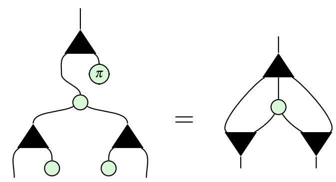
(C.9)

Proof.



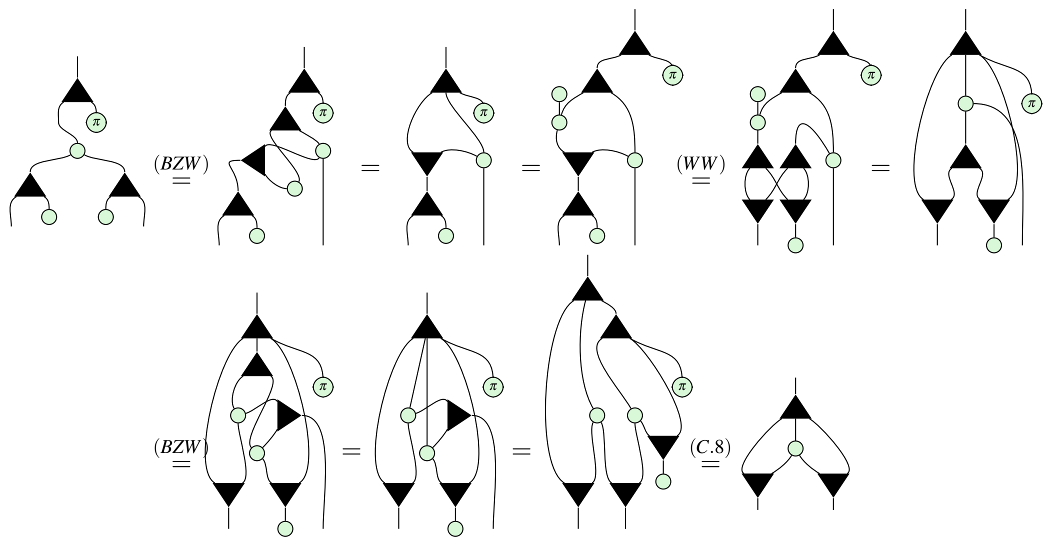
□

Lemma C.10.



(C.10)

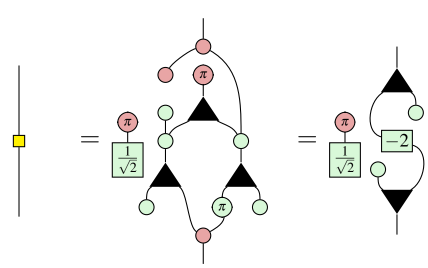
Proof.



□

Finally, we derive the axiom (HD).

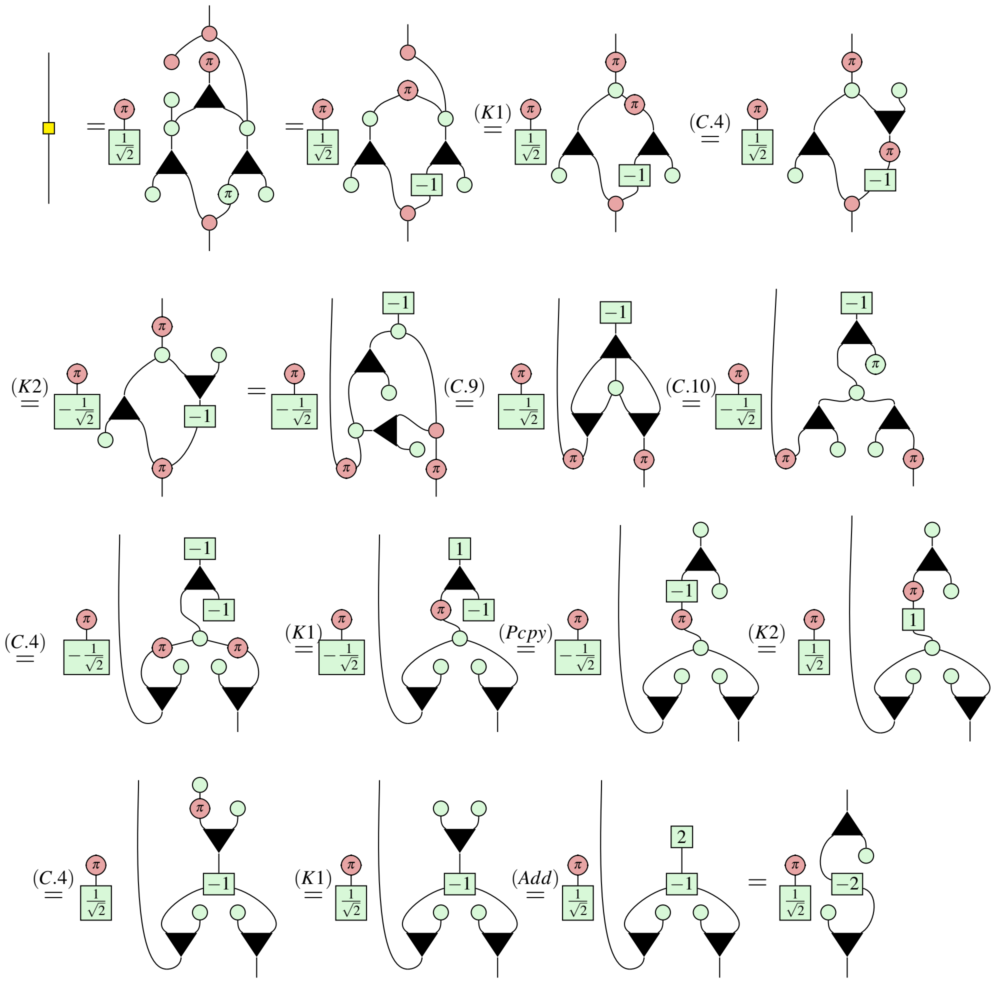
Proposition 7.



(C.11)

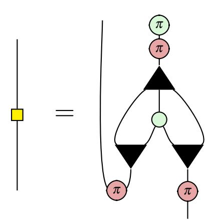
where the middle of the three diagrams is the result of restricting the (HD) axiom from [26] for arbitrary finite dimension, to the qubit (two-dimensional) setting.

Proof.



□

Remark 6. As a useful observation, compare the following diagram for the Hadamard gate derived above, to the diagram for the AND gate from Definition A.1.



This precisely agrees with its action applying a -1 phase determined by the AND of the input and output bit.

Appendix D Proofs for Section 5

D.1 Rules for controlled diagrams

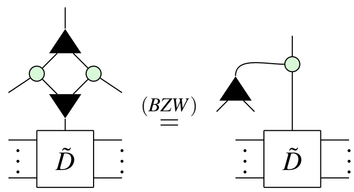
In this subsection, we verify the soundness of the axioms for controlled diagrams with respect to the interpretations.

The soundness of axioms $CM0$, $CM1$, $CS0$, and $CS1$ with respect to the interpretations in Equations (3.1) and (3.2), immediately follows from applying the control states  $= |0\rangle$ and  $= |1\rangle$ respectively.

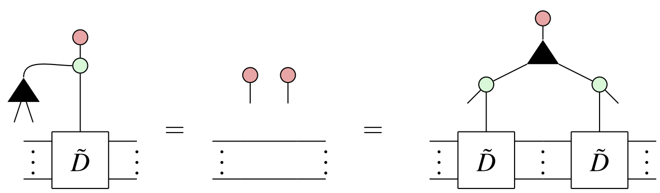
For the remaining axioms, we will also prove soundness through verifying the actions of controlled diagrams on the control states $|0\rangle$ and $|1\rangle$. This is a common technique which uniquely fixes the interpretation because $|0\rangle$ and $|1\rangle$ form a basis for the control qubit, and thus any single-qubit state can be uniquely written as a linear combination of these two states.

Confirmation of (CMcpy)

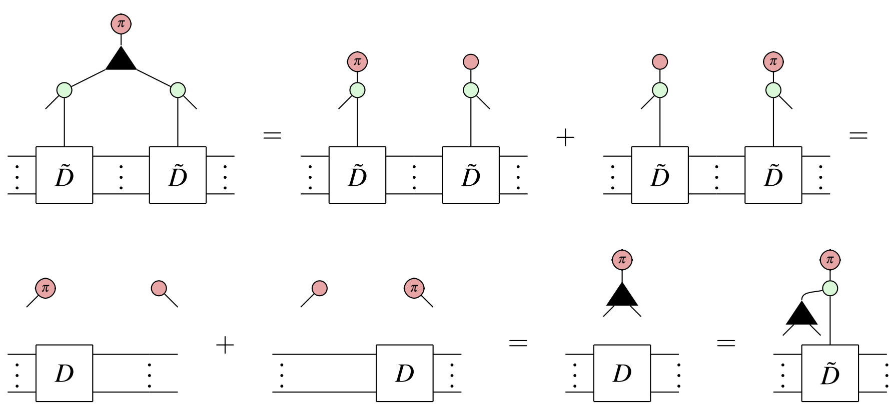
First of all, using (BZW) we can rewrite the LHS to



Then clearly



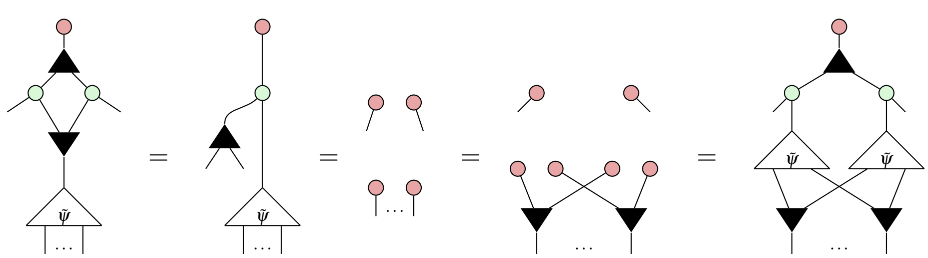
Meanwhile,



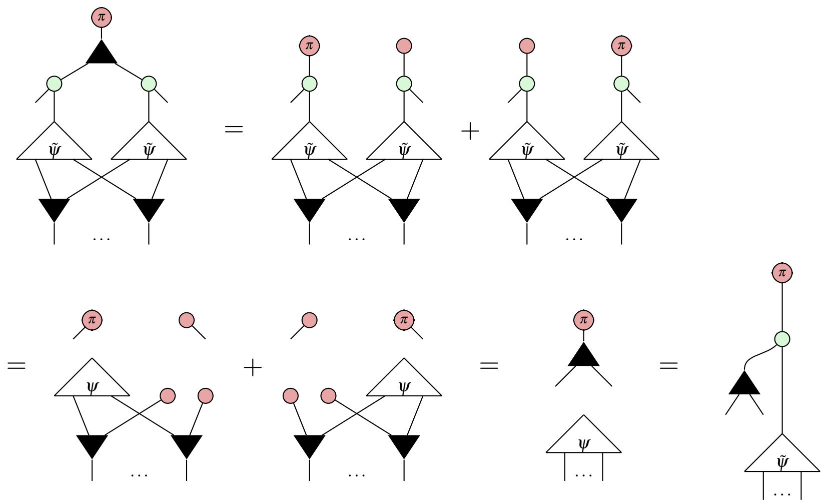
Thus the two sides are equal over the Z basis and so are equal as diagrams.

Confirmation of CScpy

As before, plugging $|0\rangle$ gives

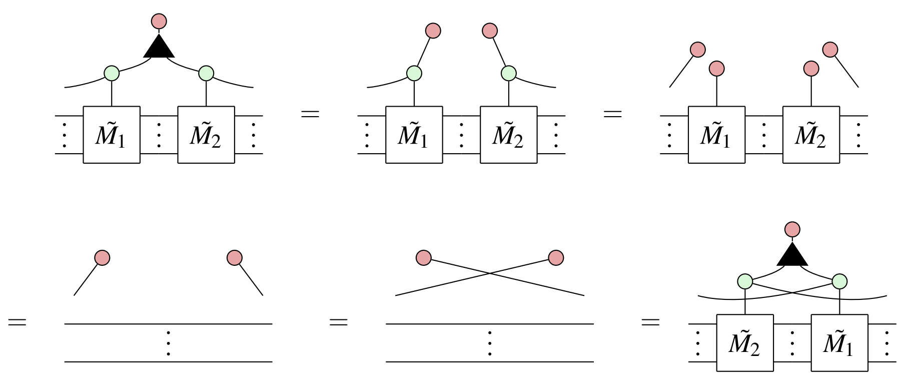


Meanwhile, plugging $|1\rangle$ gives

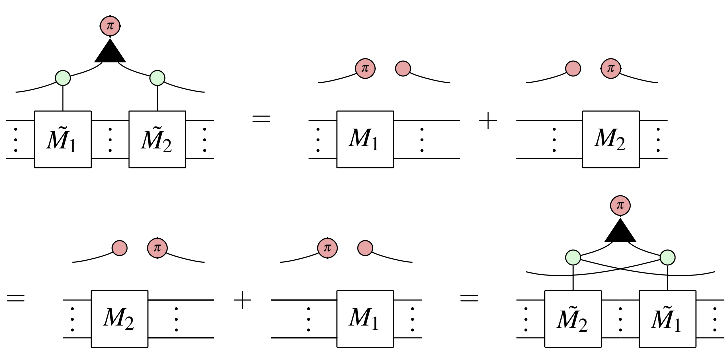


Confirmation of CMcom

Plugging $|0\rangle$ of course gives



Meanwhile, plugging $|1\rangle$ we have



D.2 Proofs for Ring Properties

Now we prove the remaining ring properties using purely diagrammatic rewrites.

$=$

$$= \; (\tilde{\psi}_1 \boxtimes \tilde{\psi}_2) \boxplus (\tilde{\psi}_1 \boxtimes \tilde{\psi}_3)$$

∎

Appendix E Proofs for Section 6

Proof of Proposition 5

Proof. We prove by induction on n.

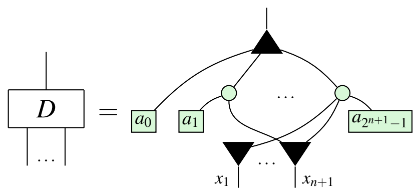
For the base case, $n = 0$. The only PNF with no outputs is a number so we have:

$$\boxed{a_0} = \begin{bmatrix} 1 & a_0 \end{bmatrix}$$

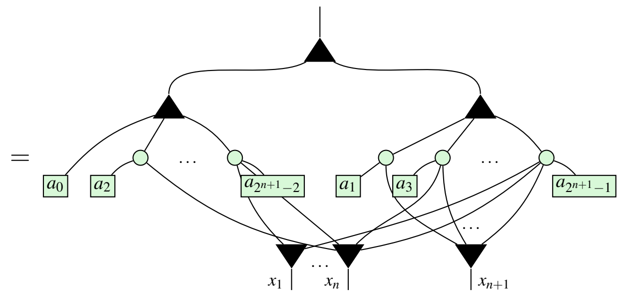
as desired.

For inductive hypothesis, we assume that Proposition 5 holds for every PNF on n outputs. We use this hypothesis to extend it to PNFs with $n+1$ outputs.

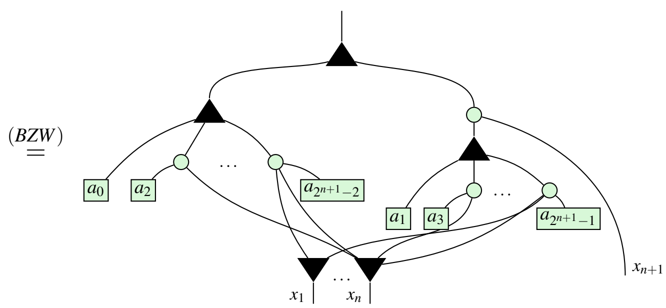
Let D be an arbitrary PNF with $n+1$ outputs. Firstly, observe that x_{n+1} is connected to only the odd coefficients $\{a_{2k+1}\}$ since these are exactly the indices with 1 in the least significant bit. Thus we can rewrite:



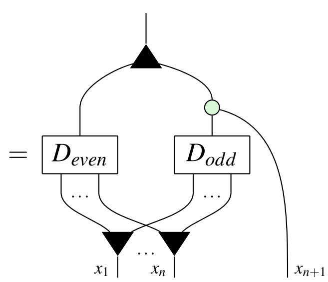
(E.1)



(E.2)



(E.3)

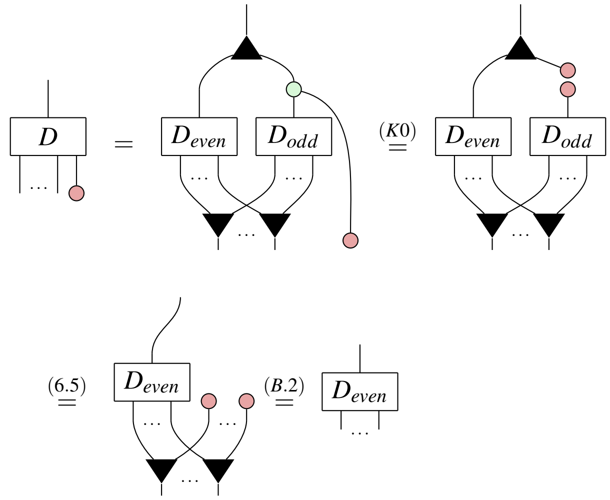


(E.4)

Where D_{even}, D_{odd} are PNF diagrams. Since they are over n variables, we can apply the inductive hypothesis and obtain:

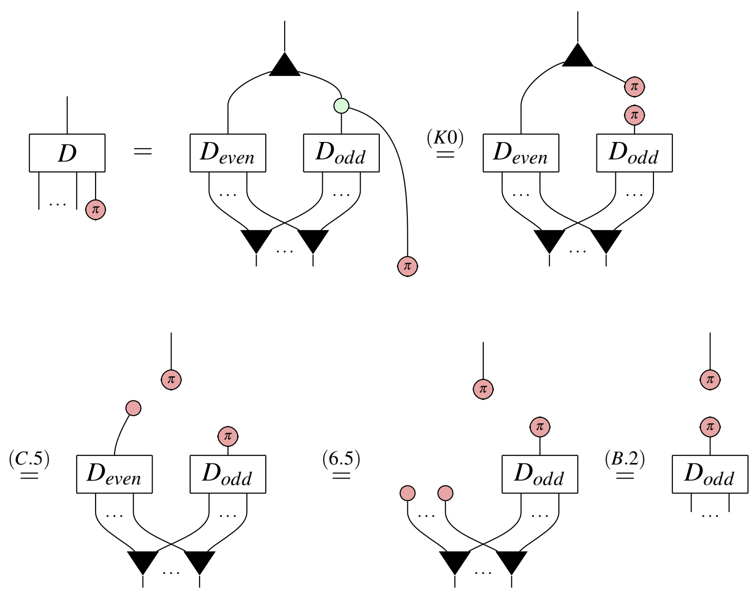
$$D_{even} = \begin{bmatrix} 1 & a_0 \\ 0 & a_2 \\ \vdots & \vdots \\ 0 & a_{2^{n+1}-2} \end{bmatrix}, \qquad D_{odd} = \begin{bmatrix} 1 & a_1 \\ 0 & a_3 \\ \vdots & \vdots \\ 0 & a_{2^{n+1}-1} \end{bmatrix} \tag{*}$$

Next, plugging red we observe:



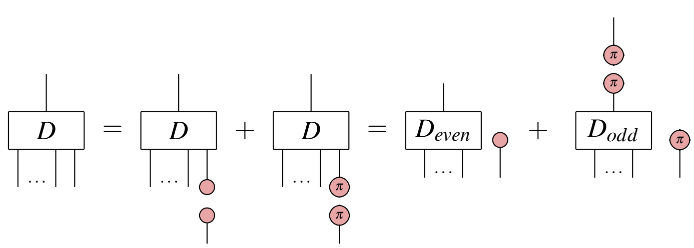
(E.5)

Meanwhile,



(E.6)

Summing these together,



(E.7)

$$= (D_{even} \otimes |0\rangle) + (D_{odd}|1\rangle\langle 1| \otimes |1\rangle) \tag{E.8}$$

$$\overset{(*)}{=} \begin{bmatrix} 1 & a_0 \\ 0 & a_2 \\ \vdots & \vdots \\ 0 & a_{2^{n+1}-2} \end{bmatrix} \otimes |0\rangle + \begin{bmatrix} 0 & a_1 \\ 0 & a_3 \\ \vdots & \vdots \\ 0 & a_{2^{n+1}-1} \end{bmatrix} \otimes |1\rangle \tag{E.9}$$

$$= \begin{bmatrix} 1 & a_0 \\ 0 & 0 \\ 0 & a_2 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & a_{2^{n+1}-2} \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & a_1 \\ 0 & 0 \\ 0 & a_3 \\ \vdots & \vdots \\ 0 & 0 \\ 0 & a_{2^{n+1}-1} \end{bmatrix} = \begin{bmatrix} 1 & a_0 \\ 0 & a_1 \\ 0 & a_2 \\ 0 & a_3 \\ \vdots & \vdots \\ 0 & a_{2^{n+1}-2} \\ 0 & a_{2^{n+1}-1} \end{bmatrix} \tag{E.10}$$

Completing the inductive step. Note that it is necessary to use a "proof-by-plugging" approach for this result, since we are proving a statement about the interpretation of a ZXW diagram as a matrix, whilst the completeness of our rule set applies only to equality of ZXW diagrams. □

Proof of Theorem 6.1

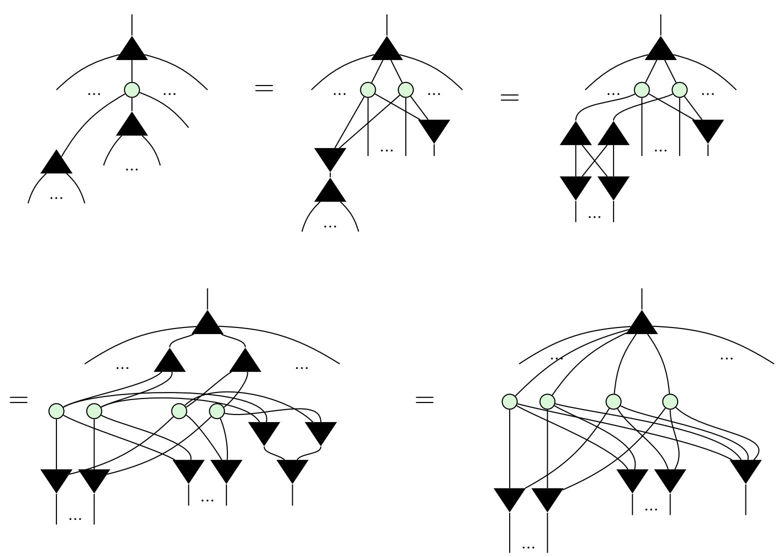
Proof. Let A be an arithmetic diagram. If $A = \boxed{a}$, we are done.

Otherwise, A has at least one output. First, we shall rewrite A into three layers, consisting of: (1) a single W at the top, (2) a layer of and (3) a layer of $\boxed{a}$'s and 's. Then we shall collect terms and order the boxes to produce a PNF.

If the top of A is not already , it must be . It cannot be $\boxed{a}$ since the remaining arithmetic diagram would then have no inputs which is impossible. It cannot be since there is only one input and arithmetic diagrams cannot contain . Thus we can rewrite:

(1) 
(1) guarantees there is a W at the top. We shall now repeatedly apply rewrites underneath the W until there are exactly three layers. Assume that fusion is applied as much as possible between each stage and (6.4) is applied and simplified with (K0) to remove whenever possible. Then for as long as there are at least 4 layers, we can apply one of the following rewrites:

(2) 
(3) 
(4) 
(5) 
(6) 
Clearly, we can only stop applying these rules once A is a sum of products of copies. Steps (2) and (3) ensure the top of A has such a structure and steps (4) - (6) ensure that there is nothing beneath the 's . To see that this will always terminate, observe that (2) preserves the depth of A while (4), (5), (6) all decrease it. (3) also preserves the depth, except for the following sub-case which can be further simplified by (5) [1].



(2) and (3) can only be applied a finite number of times before another simplification must be used, since (2) cannot create new ways to apply (3). So repeatedly applying these rewrites must eventually shrink the depth down to 3, as desired. Finally, to put A in PNF we must:

(7) Collect terms: whenever there are two boxes connected to exactly the same set of 's, use (B.6) to fuse them together.

(8) Pad: use (B.3) to insert $\boxed{0}$ for any connectivities that do not exist in A.

[1] We thank an anonymous reviewer for pointing this case out.

(9) Reorder: use (Sym) to reorder coefficients into the canonical order.

Step (7) ensures that every  has unique connectivity. Step (8) ensures there are exactly 2^n coefficients so that step (9) can order them in the appropriate way.

Thus A has been written in PNF, completing the proof.

□

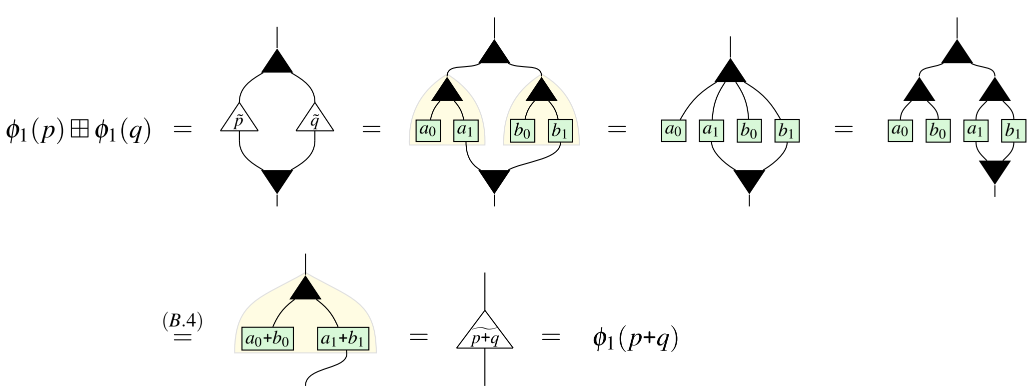
Proof of Theorem 6.2

Proof. First, we show ϕ_n is a homomorphism, i.e.

$$\forall p, q \in \mathscr{P}_n, \phi_n(p+q) = \phi_n(p) \boxplus \phi_n(q), \quad \phi_n(p \times q) = \phi_n(p) \boxtimes \phi_n(q) \tag{E.11}$$

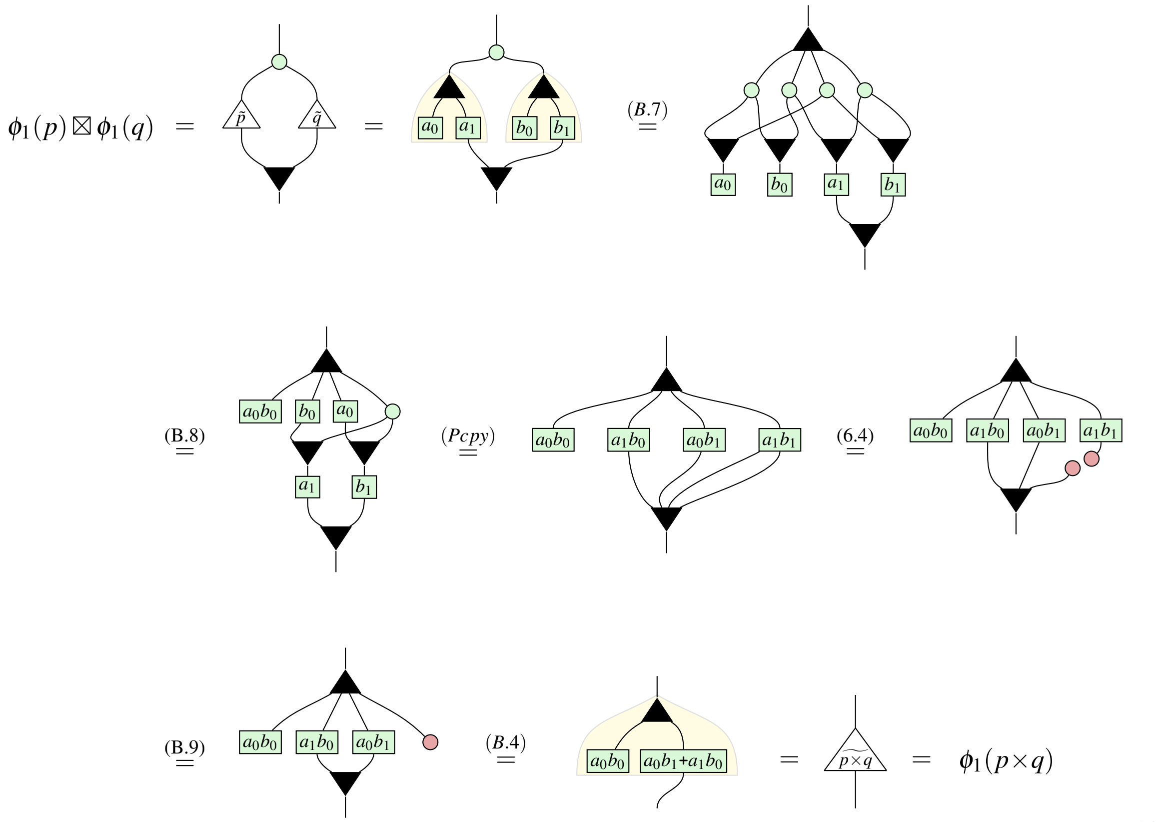
The strategy for the proof will be an induction on n. Here, the yellow shaded regions serve no purpose other than to make the subdiagram that was rewritten in the preceding or following step easier to visually identify.

Base case: We have not defined controlled states for $n = 0$, so the base case begins with $n = 1$. Let $p, q \in \mathscr{P}_1$. Write as $p(x_1) = a_0 + a_1 x_1, q(x_1) = b_0 + b_1 x_1$, where $a_0, a_1, b_0, b_1 \in \mathbb{C}$. Then since $p + q = a_0 + b_0 + (a_1 + b_1)x_1$,



(E.12)

Meanwhile, since $p \times q = a_0 b_0 + (a_0 b_1 + a_1 b_0) x_1$,



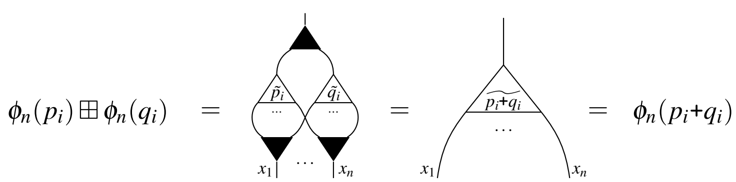
(E.13)

Completing the base case.

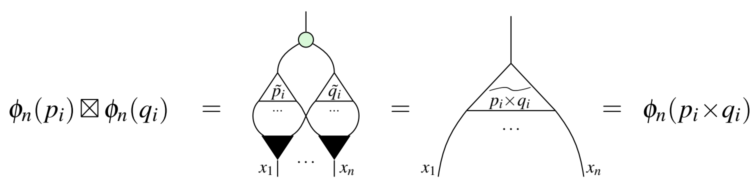
Inductive step:

Let $Hom(n)$ assert than ϕ_n is a homomorphism. Then for the inductive step we wish to prove that $\forall n, Hom(n) \implies Hom(n+1)$.

The proof relies on the recursive definition of $R[x_1, x_2] = R[x_1][x_2]$, for any ring R, to rewrite an arbitrary polynomial $p(x_1, ..., x_{n+1}) = a_0 + a_1 x_{n+1} + ... + a_{2^{n+1}-1} x_1 x_2 ... x_{n+1} \in \mathscr{P}_{n+1}$ as $p(x_{n+1}) = p_0 + p_1 x_{n+1}$, where $p_0, p_1 \in \mathscr{P}_n$. This allows the p_i to be treated similarly to the scalars in the base case. Thus the inductive hypothesis states that for all $p_i, q_i \in \mathscr{P}_n$,

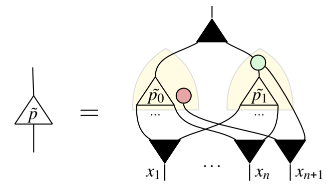


(IH1)



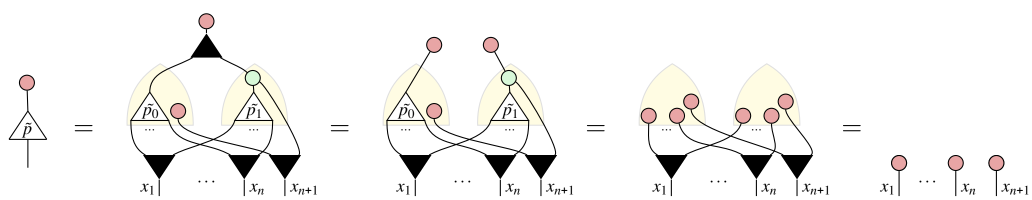
(IH2)

Let $p(x_{n+1}) = p_0 + p_1 x_{n+1}$ and $q(x_{n+1}) = q_0 + q_1 x_{n+1}$, where $p_0, p_1, q_0, q_1 \in \mathscr{P}_n$. We first verify correctness of the constructed controlled diagram

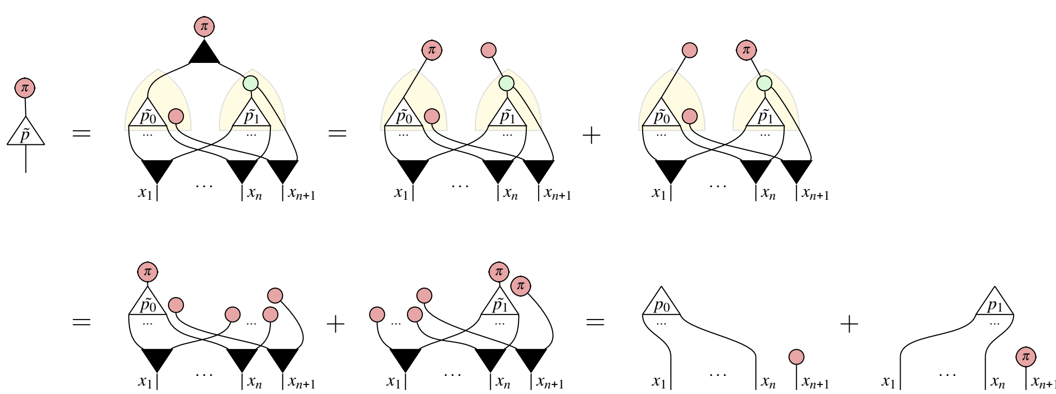


(E.14)

because it results in $|0...0\rangle$ when the control is $|0\rangle$, and in the state corresponding to p when the control is $|1\rangle$.



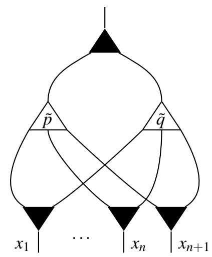
(E.15)



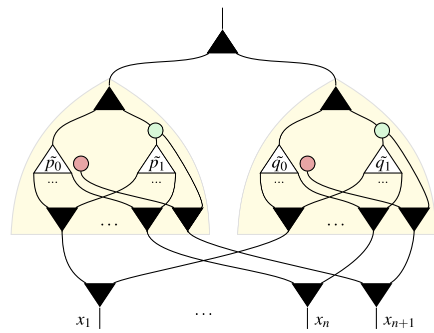
(E.16)

Applying this in the inductive step for constructing a controlled diagram of $p+q$ from those of p and q:

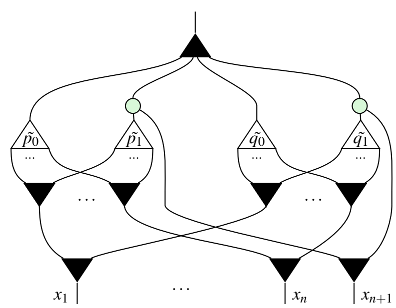
$\phi_{n+1}(p) \boxplus \phi_{n+1}(q) \quad =$



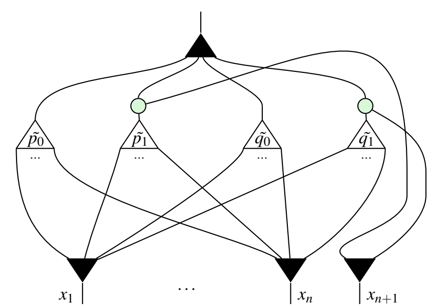
$=$



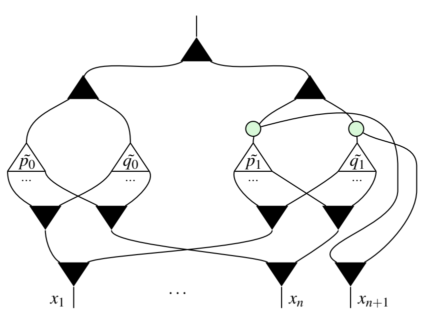
$=$



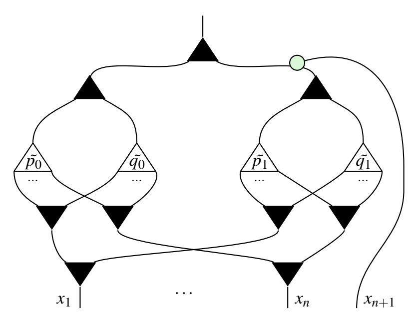
$=$



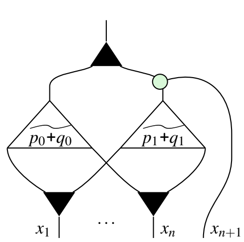
$=$



$\overset{(BZW)}{=}$



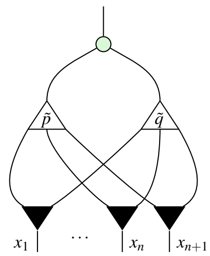
$\overset{(IH1)}{=}$



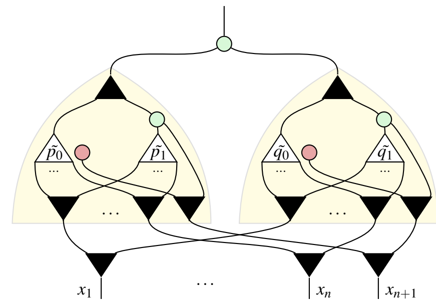
$$= \quad \phi_{n+1}\left((p_0+q_0)+(p_1+q_1)\,x_{n+1}\right) \quad = \quad \phi_{n+1}(p+q)$$

Similarly, for multiplication:

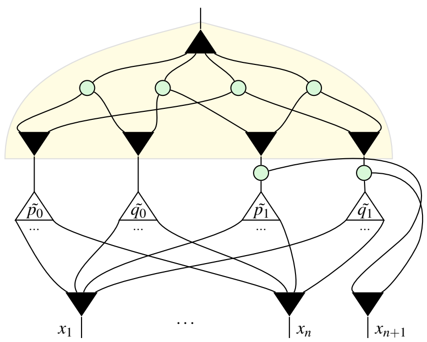
$$\phi_{n+1}(p) \boxtimes \phi_{n+1}(q) \quad =$$



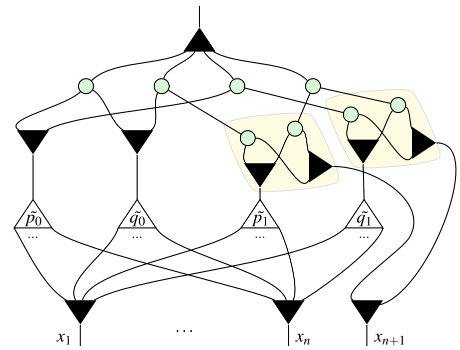
$=$



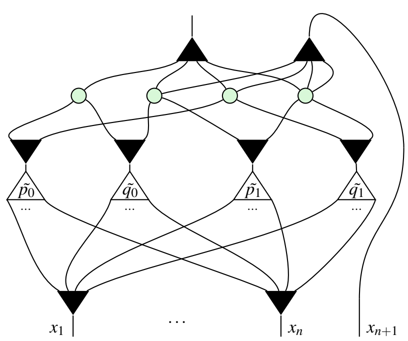
$\overset{(B.7)}{=}$



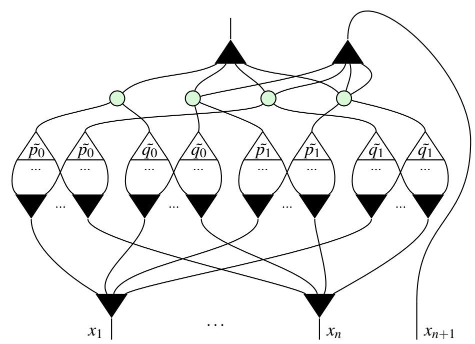
$\overset{(BZW)}{=}$



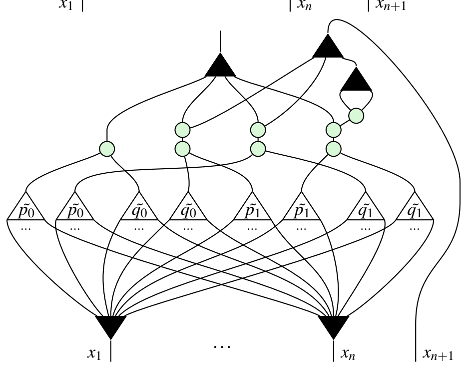
$=$



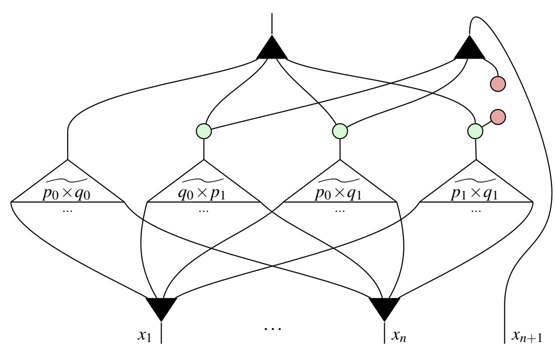
$\overset{(CScpy)}{=}$



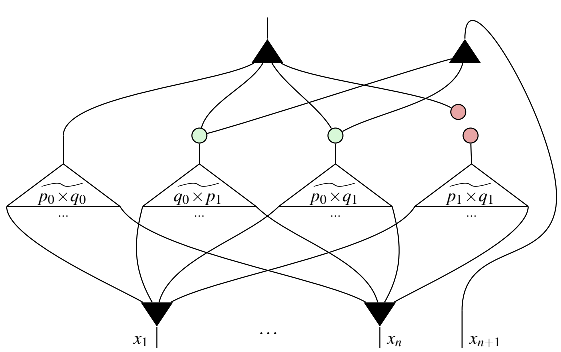
$=$



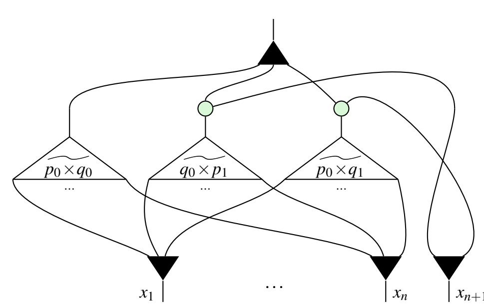
$\overset{(IH2),(6.4)}{=}$



$=$



$\overset{(CS0)}{=}$

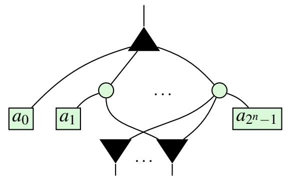


$$= \quad \phi_{n+1}\left((p_0 \times q_0) + (q_0 \times p_1)x_{n+1} + (p_0 \times q_1)x_{n+1}\right) \quad = \quad \phi_{n+1}(p \times q)$$

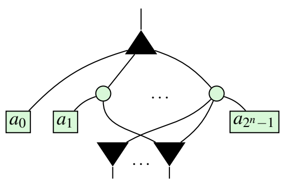
This completes the inductive step, proving that $\forall n > 1$, ϕ_n is a homomorphism.

Finally, to see ϕ_n is an isomorphism, we use Theorem 6.1 to write an arbitrary controlled state in PNF:

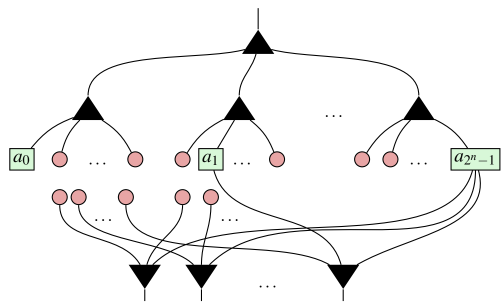
$$\begin{bmatrix} 1 & a_0 \\ 0 & a_1 \\ \vdots & \vdots \\ 0 & a_{2^n-1} \end{bmatrix} =$$



Then all we have to do is interpret it as the image of a polynomial:



$=$



$$= \phi_n(a_0) + \phi_n(a_1 x_n) + \ldots + \phi_n(a_{2^n-1} x_1 x_2 \ldots x_n)$$

$$= \phi_n(a_0 + a_1 x_n + \ldots + a_{2^n-1} x_1 x_2 \ldots x_n)$$

$\square$
